## Mutual Fund's $R^2$ as Predictor of Performance

By

Yakov Amihud<sup>\*</sup> and Ruslan Goyenko<sup>\*\*</sup>

## Abstract:

We propose that fund performance is predicted by its  $R^2$ , obtained by regressing its return on the Fama-French-Carhart four benchmark portfolios. Lower  $R^2$ , or higher idiosyncratic risk relative to total risk, measures selectivity or active management. We show that lagged  $R^2$  has significant negative predictive coefficient in predicting *alpha* or *Information Ratio*. This is consistent with Cremers and Petajisto's (2008) results on the effect of selectivity. Funds ranked into lagged lowest-quintile  $R^2$  and highest-quintile *alpha* produce significant *alpha* of 2.8%. Also, both fund *RMSE* and return volatility predict the following year's performance with significant positive and negative coefficients, respectively. Across funds,  $R^2$  is an increasing function of fund size and a decreasing function of its age, its manager tenure and its past performance, although better performance induces funds to increase their  $R^2$ .

## **1. Introduction**

Fama (1972) suggests that a portfolio's overall performance in excess of the betaadjusted return on a benchmark (or naïve) portfolio is due to selectivity, which "measures how well the chosen portfolio did relative to a naively selected portfolio with the same level of risk" (Fama, 1972, p. 557). Recent studies show that fund performance is positively affected by fund selectivity or active management, measured by the deviation of funds holdings from some diversified benchmark portfolio (see review below). The problem is that this measure of selectivity requires knowledge of the portfolio composition of all mutual funds and of their benchmark indexes, which is hard for many investors to obtain and calculate. It also hard to measure selectivity when the benchmark portfolio is not well-defines, that is, when funds opt to outperform some combination of benchmark indexes.

We propose a simple and intuitive measure of mutual fund selectivity, based on the fund's  $R^2$  from the standard 4-factor regression model of Fama-French (1993) and Carhart's (1997), which includes four factor-mimicking portfolios: *RM-Rf* (the market portfolio excess return), *SMB* (small minus big size stocks), *HML* (high minus low book-to-market ratio stocks) and *UMD* (winner minus loser stocks).  $R^2$ , the proportion of the return variance that is explained by broad portfolios or indexes, is a traditional measure of diversification, and thus  $1-R^2$  is the relative magnitude of idiosyncratic risk or selectivity. The closer is  $R^2$  to 1, the closer does the fund track the benchmark portfolios and the less is the selectivity. If selectivity enhances mutual fund performance,  $R^2$  should negatively predict the fund's performance.

This is indeed what we find:  $R^2$  has a negative and significant predictive effect on fund performance, using two conventional measures: the intercept alpha from the fourfactor regression model, and the Information Ratio, which is alpha scaled by the idiosyncratic (residual) risk from that regression. We also identify an  $R^2$ -based strategy that earns significantly positive average excess return (factor-adjusted) on mutual funds: at the beginning of each year, select funds whose previous year's  $R^2$  was in the lowest quintile and whose alpha was in the highest quintile. These funds generate a significant risk-adjusted excess return of 2.81% in the following year.  $R^2$  also captures another kind of active fund management: rotation between characteristics or factors over time, which may reflect timing. In our estimation of the four-factor model, the factors' coefficients are constant through the year, while active fund managers may change their portfolio such that it rotates between factors. Mamaysky, Spiegel and Zhang (2007) estimate the factor betas over 60-month periods by Kalman Filter and find that they vary over time. Our estimation period is only one year, during which factor rotation is naturally more limited, but such rotation can still be done to some extent.

By definition,  $R^2$  is decreasing in the regression residuals standard deviation, or *RMSE*, and increasing in the standard deviation of the fund return, which we denote by *SDR* (their squared ratio equals  $1-R^2$ ). The *RMSE* (or its square) is "tracking error," a measure of active fund management. Wermers (2003) finds that the standard deviation of S&P500-adjusted fund return is positively related to the contemporaneous fund performance, measured by the intercept *alpha* from the Carhart (1997) four-factor model. Cremers and Petajisto (2008) find that the tracking error (the standard deviation of the fund's benchmark-adjusted returns) has insignificant predictive effect on performance. However, models that estimate the performance-tracking error relationship omit *SDR*, which correlates positively with the tracking error. Such model misspecification results in a biased estimation of the effect of the tracking error on performance. Including both *RMSE* and *SDR* in the regression, we find that *RMSE* has a positive and significant predictive effect on fund performance while *SDR* has negative and significant predictive effect on fund performance. Together, these effects are summarized by the fund's  $R^2$ .

Studies of hedge fund performance have used  $R^2$  as a measure of fund strategy. Their results are similar to ours: lower  $R^2$  predicts better fund performance. Titman and Tiu (2008) point out that the negative relationship between hedge fund performance and  $R^2$  suggest that hedge fund performance is better when they do less hedging against common benchmarks, using Fung and Hsieh (2001, 2004) indices. Titman and Tiu suggest that choosing smaller exposure to factor risk reflects hedge funds managers' confidence in their abilities. Wang and Zheng (2008) define  $1-R^2$  as the "hedge fund distinctiveness index," where  $R^2$  is obtained from a regression of the hedge fund return on the return on its hedge fund style index, or on the aggregate hedge fund index, or on the Fung and Hsieh (2001) 7-factor model.

A number of studies show that fund selectivity enhance performance. Daniel, Grinblatt, Titman and Wermers (1997) analyze selectivity at the securities level, finding that securities that are picked by mutual funds outperform a characteristic-based benchmark, although the gain from stock picking approximately equals the funds' average management fee. Other studies examine selectivity at the fund level. Brand, Brown and Gallagher (2005) measure a fund active management by a divergence index, defined as the sum of squared deviations of the fund portfolio's stock weights from the market portfolio (or portfolio's deviations from the benchmark with respect to holdings the industry and sector level), using Australian data. They find that the divergence index positively predicts fund performance. Cremers and Petajisto (2008) show that Active Share, which represents the share of portfolio holdings that differ from the fund's benchmark index holdings, significantly predicts fund performance, after controlling for other fund characteristics. And, sorting funds on prior one-year performance and on Active Share, they identify a group of funds with active share and high prior performance that generates significantly positive four-factor *alpha*, after controlling for benchmark (or style) returns. Notably, these returns are net of expenses. Kacperczyk, Sialm and Zheng (2005) find that funds exhibit better performance if they have greater industry concentration of holdings compared to the weights of these industries in a diversified portfolio, and Kacperczyk and Seru (2007) find that funds whose stocks holdings are related to company-specific information from analysts' expectations exhibit better performance.

Our study examines the effect of fund selectivity on performance, using measures which do not require knowledge of the fund portfolio holdings. We proceed as follows. Section 2 presents the fund performance measures that we use and their estimation procedure, and then it presents the performance predictors that we use,  $R^2$  and its components, the residual mean-squared error and the return standard deviation. Section 3 describes data and sample selection procedure. Section 4 presents the results on the prediction of next-year fund performance, employing two performance measures – *alpha* and *InfRatio* – and various predictive methods. We also explain why the predictive power

of our measures is weaker in early period and stronger in more recent periods. In Section 5 we show how using information about past fund performance and  $R^2$  enable to choose a portfolio of funds which produces significant positive performance in the following year. Section 6 we present estimation of the association between fund characteristics and our performance predictor  $R^2$ . Concluding remarks are in Section 7.

#### 2. Fund Performance Measures and performance predictors

## 2.1. Performance measures

We employ two standard measures of fund performance. The first is the intercept  $alpha_j$  from the four-factor regression model of Fama and French (1997) and Carhart (1997),

$$R^{e}_{j,t} = alpha_{j} + \beta I_{j}(RM_{t} - rf_{t}) + \beta 2_{j}SMB_{t} + \beta 3_{j}HML_{t} + \beta 4_{j}UMD_{t} + e_{j,t}.$$
 (1)

 $R^{e}_{j,t} = R_{j,t} - r_{f,t}$  is the excess return on fund *j* in period *t* in excess of the risk-free rate, the four factors are defined above and  $e_{j,t}$  is the residual.

The second performance measure is the *Information Ratio* or the *Appraisal Ratio*, which measures the extent of the fund's excess performance relative to its idiosyncratic risk.

$$InfRatio_{j} = \frac{alpha_{j}}{RMSE_{j}} .$$
<sup>(2)</sup>

*RMSE<sub>j</sub>* is the root mean squares of the error or residual series  $e_{j,t}$  from (1). Treynor and Black (1973), who introduce the *Appraisal Ratio* in the context of the single-index (CAPM) model, show that considering an asset *j* as part of an optimal portfolio, the fraction of the investor's capital devoted to the *j*th asset is proportional to the *InfRatio*. If evaluate a mutual fund as an active investment component in an efficient portfolio rather than a sole repository of the investor's wealth, Bodie, Kane and Markus (2009, p. 262-263) show that the larger is the *InfRatio* of a fund, the greater is the demand for the fund. Following Treynor and Black (1973) they show that an optimally constructed risky

portfolio P, composed of a passive index portfolio M and an active portfolio A, has the following Sharpe ratio, SR<sub>p</sub>:

$$SR_P^2 = SR_M^2 + \left[\frac{alpha_A}{RMSE_A}\right]^2,$$

where  $alpha_A$  and  $RMSE_A$  are measured with respect to the passive index M. That is, the contribution of mutual fund A to the Sharpe ratio of the investor's portfolio is increasing in the fund's Information Ratio. Therefore, a higher fund's *InfRatio* makes the fund more attractive to investors. The Information Ratio is used as a performance measure by Brands et. al. (2005) and by Kacperczyk et al. (2005).

The use of the Information Ratio mitigates the survivorship bias in studies of persistence in mutual funds performance. Brown, Goetzmann, Ibbotson and Ross (1992) note that choosing a risky strategy may result in high *alpha* but it also increases the probability of failure. Because we observe the survivors, the apparent pattern is that of persistence of high performance and ex post, superior *alphas* are positively related to idiosyncratic risk. Therefore, scaling *alpha* by the fund idiosyncratic risk reduces the survivorship bias.<sup>1</sup> The Information Ratio, which scales the abnormal fund performance by the volatility of the abnormal fund returns, mitigates this bias.

In summary, we estimate for each fund both *alpha* and *InfRatio* and analyze how these performance measures can be predicted by various fund characteristics.

## **2.2 Performance predictors**

We predict fund performance in one period by its estimated  $R^2$  in the preceding period, where  $R^2$  is estimated from the regression model (1). As detailed below, because we use daily data and because some stocks that constitute the fund returns are slow to adjust to information, we use in practice the regression model (1) where the fund return is regressed on the current and one-lag returns of the benchmark indexes (following Dimson (1979)). We also use as predictors the two components of  $R^2$  (in squared-root values): *RMSE*, the residual standard deviation from (1), and *SDR*, the standard deviation of the excess fund return  $R^e$ .

<sup>&</sup>lt;sup>1</sup> Brown, Goetzmann and Ross (1995) show that the magnitude of the survivorship bias in the calculation of average stock returns is an increasing function of the return volatility.

## 3. Data and Sample Selection

We use the CRSP Survivorship Bias Free Mutual Fund Database with the CDA/Spectrum holdings database and merge the two databases using Mutual Fund Links tables available at CRSP. The monthly returns for mutual funds are from the CRSP Mutual Fund Database from 1989 to 2007. These are net returns, i.e. after fees, expenses, and brokerage commissions but before any front-end or back-end loads. The daily returns from 1989 to 1998 are obtained from the International Center for Finance at Yale School of Management.<sup>2</sup> These data include Standard and Poor's database of live mutual funds.<sup>3</sup> The S&P data are not survivorship-bias free. They are supplemented by another daily database which is used by Goetzmann, Ivkovic, and Rouwenhorst (2001) and obtained from the Wall Street Web. This combined database is survivorship-bias free and is also used by Cremers and Petajisto (2008). CRSP data on daily mutual fund returns begins in March, 1998. Therefore, from 1999 to 2007 we use the CRSP daily data. Altogether, our final sample spans the period from January 1989 to December 2007.

The CRSP database also contains data on total net assets, the fund's turnover ratio, expense ratio, investment objective, and other fund characteristics. We use the end-of-year values of these variables. We also use Cremers and Petajisto (2008) Active Share measure, for which data are identified only if they have reported share holdings on CDA/Spectrum. The criteria for fund selection with Active Share estimated are the same as in Cremers and Petajisto (2008).<sup>4</sup>

The CRSP database identifies each shareclass separately, whereas the CDA database lists only the underlying funds. The Mutual Fund Links tables reliably assign each shareclass to the underlying fund. Whenever a fund has multiple shareclasses at the CRSP database, we compute the weighted CRSP net returns, expenses, turnover ratio and other characteristics for each fund. The weight is based on the most recent total net assets of that shareclass.

<sup>&</sup>lt;sup>2</sup> We are grateful to William Goetzmann for providing these data.

<sup>&</sup>lt;sup>3</sup> This is also previously known as Micropal mutual fund data

<sup>&</sup>lt;sup>4</sup> We are grateful to Martijn Cremers and Antti Petajisto for providing the Active Share data which are available from 1980 to 2006.

Our analysis employs actively managed all-equity funds. We therefore include funds with investment objective codes from Weisenberg and Lipper to be aggressive growth, growth, growth and income, equity income, growth with current income, income, longterm growth, maximum capital gains, small capitalization growth, micro-cap, mid-cap, unclassified or missing. Whenever Weisenberg or Lipper codes are missing, we use Strategic Insight Objective Code to identify the style. Whenever Weisenberg, Lipper or Strategic Insight Objective Code are missing, we use investment objective codes from Spectrum, if available, to identify the style. If no code is available for a fund-year and a fund has a year with the style identified, that fund-year is assigned the style of the previously identified style-year. If the fund style cannot be identified it is not included in the sample.<sup>5</sup> We then classify funds into four style categories which roughly follow the categorizations in Brown and Goetzmann (1997): (i) "Growth" which includes: Aggressive growth, Growth, Long-term growth, Maximum capital gains, (ii) "Income", (iii) "Growth and Income", (iv) "Small cap" which includes: small cap, small-cap growth, micro-cap, mid-cap. We eliminate index funds by deleting those whose name includes the word "index" or the abbreviation "ind". Following the suggestion of Elton, Gruber and Blake (1996) that inclusion of funds with total net asset value (TNA) below \$15 million can cause survivorship bias in estimation because of reporting conventions, we eliminate funds with TNA less than \$15 million at the end of the year preceding the test year. Addressing Evans's (2004) comment on incubation bias, we eliminate observations before the reported starting year by CRSP. And, following Cremers and Petajisto (2008), we delete funds with missing name in CRSP. We require funds to have at least 125 daily return data in the first year of two consecutive years, which we use to estimate lagged values of  $R^2$ , return variances and *alpha*, and only 50 daily return data in the second year, where we estimate the fund performance measures *alpha* and *InfRatio*.<sup>6</sup> The small number of days in the performance year minimizes the survivorship bias problem. We also require funds to have data in the year before the test year on expenses, turnover, total net assets, age and managerial tenure.

<sup>&</sup>lt;sup>5</sup> We identified about 5% of fund-years with missing styles.

<sup>&</sup>lt;sup>6</sup> Cremers and Petajisto (2008) require 125 days in the performance estimation year (the second of the twoyear pair). The results do not materially change under this requirement.

For the funds that satisfy these requirements, we estimate their  $R^2$  from a regression of model (1) for the first year of the two-year pair, using the indexes' current and one-day lagged returns, following Dimson (1979). We rank all resulting  $R^2$  estimates and symmetrically trim the top and bottom 1% of the observations. The funds with  $R^2$  near 1.0 are effectively "closet indexers" while very low  $R^2$  represents an outlier-type strategy or estimation error. We thus obtain a final sample of 16,646 fund-year pairs of 2,314 funds with  $R^2$  ranging between 0.240 and 0.989. This is the sample that we analyze. The mean  $R^2$  is 0.86 and the median is 0.90. Finally, we apply a logistic transformation,

 $TR^2 = log[\sqrt{R^2/(1-\sqrt{R^2})}].$ 

The resulting distribution of  $TR^2$  is fairly symmetric, as opposed to the distribution of  $R^2$ , which is concentrated in high values of  $R^2$ . As an alternative to  $R^2$ , we use the components of  $R^2$ : *RMSE*, the root mean squared error of the regression from which we estimate  $R^2$ , and the fund's return standard deviation, *SDR*.

The control variables in the predictive cross-fund regression are those that commonly appear in studies of fund performance, see e.g. the recent study by Cremers and Petajisto (2008). They include Total Net Assets, *TNA*, (\$mm), *Expenses*, which is the expense ratio of the most recently completed fiscal year,<sup>7</sup> *Turnover* or turnover ratio defined as the minimum of aggregated sales or aggregated purchases of securities divided by the average 12-month *TNA* of the fund. Among other fund characteristics we use fund age, *Age*, computed as the difference in years between current date and the date the fund was first offered, and manager tenure, *Manager Tenure*, the difference in years between current date and the date when the current manager took control. An important predictor of future performance is lagged *alpha* or *InfRatio* which may reflect managerial skill and strategy and is shown to be a significant predictor of future performance (see Brown and Goetzmann (1995) and Gruber (1996)).

## **INSERT TABLE I**

Table I presents the statistics of our sample. Panel A presents fund characteristics, while Panel B presents the correlations between them. We observe that  $R^2$  is larger for large funds, which cannot be niche investors and must hold a broad portfolio, which

<sup>&</sup>lt;sup>7</sup> Expense ratio is the ratio of total investment that shareholders pay for the fund's operating expenses, which include 12b-1 fees. Expense ratio may include waivers and reimbursements, causing it to appear to be less then the fund management fee.

makes their performance closer to that of broad indexes. Funds with more idiosyncratic investment – being more active – have higher expense ratio, as evident from the negative correlation between  $R^2$  and *Expenses*. A more detailed analysis of the relationship between  $R^2$  and the other control variables is presented in Table IX.

## 4. Fund Performance prediction in cross-sectional regressions

We study the relationship between fund performance and  $R^2$  by regressing the fund annualized *alpha* from Model (1) and *InfRatio* (Information Ratio) defined in (2) on the fund's previous-year  $TR^2$  (logistic transformation of  $R^2$ ) and control variables. All fund characteristics that are used to predict performance are known at the end of year *y*-*1* and performance is measured over the following year *y*.

## 4.1. Fund alpha as measure of performance

Table II presents the results of pooled panel regressions. As an alternative to  $TR^2$  we use *RMSE* and *SDR*, the regression mean squared error and the excess return's standard deviation, which constitute the components of  $TR^2$ . We estimate the performance over the 18 years, 1990-2007 (the first year for parameter estimation is 1989). We estimate a pooled regression with year dummy variables and style dummy variables (using the four style variables discussed above); errors are clustered at the fund level.

## **INSERT TABLE II**

The estimation results in Table II, column (1) show that  $R^2$  is a strong predictor of *alpha*. The coefficient of  $TR^2$  is –0.680 with t = 7.69. This means that funds with low  $R^2$ , which may be more active in pursuing stock selection strategies, have better performance.  $R^2$  is a decreasing function of *RMSE* from regression (1) and an increasing function of *SDR*, the standard deviation of the fund excess return  $R^e_t$ . In column (2) we estimate the effect of the components of  $R^2$  on *alpha*. The coefficient of *RMSE* is 3.955 (t = 6.33) and the coefficient of *SDR* is -6.688 (t = 19.28). This pair of results is consistent with the results on the negative effect of  $R^2$ . The result on the positive effect of *RMSE* should be compared to results in previous studies that use *RMSE* as a measure of "tracking error" and thus a proxy for fund active management or selectivity. Previous studies on the effect of *RMSE* obtain mixed results, partly because they suffer from the omitted variable bias,

having omitted the total fund risk *DSR* which is positively correlated with *RMSE* and has negative coefficient.

The effect of fund size (*TNA*) on performance is negative, although this negative effect is mitigated for very large funds, as evident from the positive and significant coefficient of  $log(TNA)^2$ . *Expenses* negatively affect performance, as observed by Gruber (1996). Given that  $R^2$  is negatively correlated with *Expenses* (see Table I, Panel B), we re-estimate the model excluding the variable *Expenses*. The coefficient of  $TR^2$  changes very little, remaining negative and highly significant. The effect of *Manager Tenure* is negative, meaning that managers who are longer time on the job generate worse performance. However, the coefficient is not statistically significant. We revisit the effect of this variable later in this paper.

The superior performance of funds with higher  $R^2$  is consistent with the findings of Cremers and Petajisto (2008) on higher performance of funds with active management, measured by AS (Active Share), the sum of absolute deviations of the fund's stock holdings (weights) from those of its benchmark portfolio. We replicate their result in column (3): AS has a positive coefficient, 1.579, with t = 3.01. The sample decreases to 1,890 funds because the calculation of AS requires fund portfolio holdings data. When including both  $TR^2$  and AS in the regression (column 4),  $TR^2$  retains its negative and highly significant effect while the coefficient of AS becomes insignificant (with negative sign). Similarly, the effects of RMSE and SDR remain practically unchanged when AS is included in the model (column 5).

In the rest of the table, we split the sample into two nine year subperiods. The year 1999, which begins the second subperiod, coincides with the beginning year of CRSP data. The first nine-year subperiod (1990-1998) has <sup>1</sup>/<sub>4</sub> of the sample fund years while the second subperiod (1999-2007) that utilizes CRSP data has <sup>3</sup>/<sub>4</sub> of the sample fund years. The results show that in the first subperiod,  $TR^2$  is insignificant and also *RMSE* is insignificant, while *SDR* retains its negative and significant effect. We explain the weak performance of  $TR^2$  during the first nine-year period in Section 4.3 below. In the recent nine-year subperiod that includes most of the data,  $TR^2$  has a negative and highly significant effect on *alpha*, and the pair *RMSE* and *SDR* have the expected signs –

positive and negative, respectively – with high level of statistical significance. The results obtained for the whole sample hold stronger for the last nine years of the sample.

## 4.2. Information Ratio as measure of performance

The second performance measure is the fund's Information Ratio,  $InfRatio_j = alpha_j/RMSE_j$ . Theoretically, the demand for an additional asset by an investor who holds an efficient portfolio is an increasing function of the asset's InfRatio. Dividing *alpha* by *RMSE* also mitigates the survivorship bias (see discussion in Brown, Goetzmann, Ibbotson and Ross (1992)). We estimate whether InfRatio is affected by the fund's lagged  $TR^2$  or its *RMSE* and *SDR*, controlling for other fund characteristics.

## INSERT TABLE III HERE

The results in Table III show that  $TR^2$  has negative and highly significant effect on the following year fund's *InfRatio*. *RMSE* and *SDR* also predict fund performance with positive and negative coefficients, respectively, which are highly significant for the entire period. As before, the effect is stronger in the second subperiod than it is in the first. For  $TR^2$ , its negative effect in the first subperiod is more significant than it was in Table II.

Active Share, AS, is a positive and highly significant predictor of *InfRatio* for the whole sample (column (3)) and it remains so after including in the model either  $TR^2$  or *RMSE* and *SDR*. However, its coefficient flips signs between the two subperiods, being negative in the first. Overall,  $TR^2$  consistently predicts the fund *Information Ratio* for the whole sample, for the two subperiods and controlling for various fund characteristics as well as for *Active Share*. The effects of fund *Expenses* size (*TNA*) is similar to that in the *alpha* model.

## 4.3. Why is the predictive power of $R^2$ stronger in recent years than in early years?

Our results show that during the first nine years of the sample (Period 1), the coefficient of  $TR_{j,y-1}^2$  as predictor of  $a_{j,y}$  is negative but small and insignificant, while in the second nine-year period (Period 2), the coefficient  $TR_{j,y-1}^2$  is more negative and statistically it is highly significant. Notably, there is a big difference in the sample size and data source between the two periods. Period 1 has 3,999 fund years while Period 2 has 12,647 fund years, more than 3 times greater. The data source for Period 2 is CRSP, which provides broader data which may be more reliable. In addition to that, we propose the following explanation.

We want to measure the relationship between the fund performance  $(a_{j,y})$  in year y and the fund's strategy for that year, the *planned*  $R^2_{j,y}$ , using  $R^2_{j,y-1}$  as an estimate of  $R^2_{j,y}$ . This follows, for example, the convention in asset pricing empirical procedure such as that of Fama and MacBeth (1973) who use lagged portfolio  $\beta$  as an instrument for the current  $\beta$ . But if  $R^2_{j,y-1}$  is a poor predictor of  $R^2_{j,y}$ , this procedure produces poor results on the relationship between performance and *planned*  $R^2_{j,y}$ .

Indeed, we observe that in Period 1,  $Corr(TR^2_{j,y}, TR^2_{j,y-l})$  is far lower than in Period 2, and therefore in Period 1,  $TR^2_{j,y}$  is a poor predictor of  $\alpha_{j,y}$ . We do an annual regression

$$TR_{j,y}^2 = b_{0,y} + b_{1,y} TR_{j,y-1}^2 + e_{j,y}$$

for y = 1990, 1991, ... 2007 and obtain the following results for the average *R-sqr* from these regressions:

**Period 1**, 1990-1998: Average *R*-*sqr* = 0.24. Median *R*-*sqr* = 0.28.

**Period 2.** 1999-2007: Average R-sqr = 0.62. Median R-sqr = 0.70.

These estimations means that in the second nine-year period,  $R_{j,y-I}^2$  is a more reliable (less noisy) estimate of the fund's next year's  $R_{j,y}^2$ . This accounts at least partially for the greater significance of performance prediction by lagged  $R^2$  in Period 2 that we observe in Tables II and III.

We further do the following regression for the entire 18-year period. Define PERIOD2 = 1 for the years 1999-2007. Then,<sup>8</sup>

<sup>&</sup>lt;sup>8</sup> In the following regressions, *t*-statistics are based on standard deviations clustered by funds.

$$TR_{j,y}^2 = 0.524 TR_{j,y-1}^2 + 0.227 PERIOD2*TR_{j,y-1}^2 + \text{year dummy variables}$$
  
(23.73) (9.94)

The positive and significant coefficient of  $PERIOD2*TR_{j,y-1}^2$  means that during Period 2, there is a rise of 43% in persistence in  $R_j^2$  between the years compared to the persistence in Period 1. We also estimate the model in as panel regression:

$$TR_{j,y}^2 = 0.178 TR_{j,y}^2 + 0.136 PERIOD2*TRI_{j,y}^2 + year fixed effects$$
  
(7.67) (5.73) + fund fixed effects

This estimation shows that the persistence in funds'  $R_j^2$  over time is higher by 76% in Period 2 than it is in Period 1. Notably, it is in Period 2 that funds'  $R_{j,y-1}^2$  strongly predicts year-y performance.

## 4.4. Fund Fixed Effects

Table IV presents estimations with fund *fixed effects*, which effectively remove interfund differences that relate to fixed fund characteristics that could account for the negative performance- $TR^2$  relationship. Here, the hurdle is raised because if a fund has a constant strategy that results in low  $R^2$ , its performance will be captured by its fixed effect and will not show as a function of its  $R^2$ .

## INSERT TABLE IV

The estimation results with fund fixed effect show that  $TR^2$  significantly predicts fund performance, measured either by *alpha* or by *InfRatio*. Higher  $TR^2$  predicts lower performance in the following year, after controlling for fund characteristics, both those that are fixed and those that vary over time. *RMSE* and *SDR* too are significant predictors of fund performance. In this regression, *Expenses* is insignificant because it changes very little for a given fund. The results also show that as the fund becomes larger, its performance deteriorates. The coefficient of Log(TNA) is negative and significant, but this effect is attenuated as the fund becomes very large, as evident from the positive and significant coefficient on  $Log(TNA)^2$ .

Estimating the effect of Active Share in a fixed-effect regression which excludes  $TR^2$ , we obtain that its coefficient in the *alpha* regression is negative and significant, and when

adding Active Share to the *alpha* regression that includes  $TR^2$ , its coefficient is again negative and significant, while  $TR^2$  retains its negative and significant coefficient. When adding Active Share to the *alpha* regression that includes *RMSE* and *SDR*, its effect is negative and significant, while the results for *RMSE* and *SDR* are qualitatively unaltered. In the *InfRatio* equations, Active Share has positive but statistically insignificant coefficient in the fixed-effect regressions.

## 4.5. Annual cross-sectional regressions (Fama-MacBeth procedure)

We now estimate the predictive power of  $TR^2$  and the pair *RMSE* and *SDR* by the Fama-MacBeth (1973) procedure, performing annual cross-sectional estimates which allow the slope coefficients of the explanatory variables to vary over time. The control variables are the same as in the previous regression, including the style dummy variables.

#### **INSERT TABLE V**

The results in Table V are consistent with the previous results although they are not always as statistically significant.  $TR^2$  has a negative predictive effect on *alpha* and its average coefficient is significant at the 6% level. The lower statistical significance may be due to the fact that in this procedure, all years have the same weight regardless of the number of funds in each, while in the pooled panel regression, the estimation results are largely influenced by the number of observations (fund-years) in recent years which is much greater than in earlier years, and it is in recent years that the negative *alpha-TR*<sup>2</sup> is more significant. Still, in a binomial test for the coefficient of  $TR^2$  being negative against the null that it is equally-likely to be positive or negative, the null is rejected at the 0.05 level. Another feature of this procedure that may account for the results is the coefficient of all control variables are allowed to vary between years. In this estimation, only the coefficients of *Expenses* and lagged *alpha* are statistically significant.

Measuring fund performance by *InfRatio*, the coefficient of  $TR^2$  is negative and significant at the 0.01 level. The binomial test too rejects the null hypothesis that the coefficient of  $TR^2$  is equally likely to be positive or negative in favor of the alternative hypothesis that the coefficient of  $TR^2$  is negative.

*RMSE* and *SDR* have the expected signs – positive and negative, respectively – in both the *alpha* model and in the model of *InfRatio*. However, their coefficients are statistically significant only in the *InfRatio* regression.

# 4.6. Testing for nonlinearity in the predictive effects of $R^2$ , alpha and InfRatio and interaction effects

4.6.1. Asymmetric effects of  $R^2$ , alpha and InfRatio above and below median

We now examine non-linearity in the predictive performance of both  $R^2$  and *alpha* or *InfRatio*. In the first year of each two-year pair we divide  $R^2$  into those above and below the median for the year. The dummy variable  $HiDUMR^2 = 1$  if  $R^2$  is above the median for the year. Then we split  $TR^2$  into  $HiTR^2 = HiDUMR^{2*}TR^2$  and its complement  $LoTR^2 = (1 - HiDUMR^2)*TR^2$ . We follow the same procedure with *alpha*, splitting it in each year above\below the median into *Hialpha* and *Loalpha*, with the related dummy variable HiDUMalpha, and with *InfRatio*, creating the variables HiDUMInfRatio, HiInfRatio and LoInfRatio. We then estimate the models that we have estimated before, replacing  $TR^2$  and *alpha* (or *InfRatio*) by the respective three variables which allow for different intercept and different slope coefficients for values above and below the median.

### **INSERT TABLE VI**

The results in column (1) of Table VI show that in the *alpha* equation, the effects of both  $TR_{y-1}^2$  and *alpha<sub>y-1</sub>* on *alpha<sub>y</sub>* are non-linear, with their above-median values having weaker predictive effects (in absolute term) than their below-median values. The coefficient of  $HiTR^2$ , while negative and significant, is less negative than the coefficient of  $LoTR^2$ , and the coefficient of *Hialpha* is less positive than the coefficient of *Loalpha*. The overall median of  $R_{y-1}^2$  is 0.90 and its maximum is 0.989, leaving smaller variance in its above-median values (note, however, that the transformation into  $TR^2$  increases the variance of above-median values). The below-median values of  $R_{y-1}^2$  range from 0.24 to 0.90, and it is for this range that there is a more negative predictive effect of  $TR_{y-1}^2$  on *alpha<sub>y</sub>*. As for lagged *alpha*, *Loalpha<sub>y-1</sub>* has much stronger predictive power on *alpha<sub>y</sub>* than does *Hialpha<sub>y-1</sub>*, implying greater persistence of bad performance, a pattern noted by Gruber (1996) who predicts alpha by the rank of lagged alpha. However, in the InfRatio model, column (4), there are no asymmetric effects. The coefficients of  $HiTR^2$  and  $LoTR^2$  are very similar, both being negative and significant. Nor is there asymmetry in the effects of HiInfRatio and LoInfRatio, both having positive and significant coefficients which are almost the same. Weighting *alpha* by *RMSE*, which produces *InfRatio*, seems to eliminate the asymmetry in performance prediction.

## 4.6.2. Interaction effects or $R^2$ with alpha and Manager Tenure

We examine the interaction predictive effect of  $TR^2$  with *alpha* and with managerial tenure in column (2). The question is whether the effect of selectivity or idiosyncrasy employed by funds depends on their past performance. The pattern of the mean *alpha* when funds are sorted by their lagged  $R^2$  and *alpha* (Panel A in Tables VII and VIII below) suggests that among the weakly-performing funds, lower  $R^2$  predicts worse *alpha*. We therefore include in the model the interaction term *alpha<sub>v-1</sub>\*TR*<sup>2</sup> or *InfRatio\*TR*<sup>2</sup>.

Another hypothesis relates to the connection between manager tenure and fund strategy. Chevalier and Ellison (1999) propose that a fund manager's propensity to take unsystematic risk is positively related to her age, which we translate here to managerial tenure. We therefore add to the model the interaction term  $Log(Manager Tenure)*TR^2$ .

The estimated effects of these two interaction terms are presented in column (2) for the *alpha* model and in column (5) for the *InfRatio* model. The results are:

- (a) The coefficients of  $alpha*TR^2$  and of  $InfRatio*TR^2$  are negative end significant, meaning that that the negative effect of  $TR^2_{y-1}$  on performance is stronger for funds that have been performing better in the past year. That is, selectivity enhances performance in funds with better track record of performance.
- (b) The coefficients of  $Log(Manager Tenure)*TR^2$  are positive and significant, meaning that the positive effect of selectivity (low  $TR^2_{y-I}$ ) on performance is stronger in funds with newer managers. The coefficient of Log(Manager Tenure) in itself is negative and significant as opposed to being insignificant in Tables II and III, implying a detrimental effect of longevity in the fund on performance.

Notably, in both these equations, the negative effect of  $TR^2$  is negative and highly significant.

Finally, columns (3) and (6) combine the models of the non-linear effects of  $TR^2$  and *alpha* or *InfRatio* with the two interaction effects. The results remain qualitatively the same as for each model separately. Focusing on the effect of  $TR^2$ , it remains negative and highly significant for both above and below median values, with its effect being attenuated for funds with longer-tenure managers and funds with bad past performance.

## 5. Fund performance based on sorting on lagged $R^2$ and performance

We examine whether we can identify and predict a group of funds with significant positive performance. In each year y we sort funds into five portfolios by their  $R^2$  in y-l and within each quintile we sort them into five portfolios by their *alpha* (or *InfRatio*) in y-l. Then, for each of the resulting 25 portfolios we estimate the average *alpha* (or *InfRatio*) for year y.

## INSERT TABLE VII

Panel A of Table VII reports the average portfolio *alpha* and Panel B reports the average portfolio *InfRatio*. Consider Panel A. Average *alpha<sub>y</sub>* is increasing in *alpha<sub>y-1</sub>* and decreasing in  $R^2_{y-1}$ , as it is in the regressions. Out of the 25 portfolios we identify two fund portfolios with high *alpha<sub>y-1</sub>* and the lowest low  $R^2_{y-1}$  which have positive and significant *alpha<sub>y</sub>*. In particular, the highest *alpha<sub>y-1</sub>*-lowest  $R^2_{y-1}$  portfolio produces annual alpha of 2.81% with t = 5.84. Also, among the highest *alpha<sub>y-1</sub>* portfolios, the middle  $R^2_{y-1}$  portfolio has positive and significant *alpha<sub>y</sub>*. However, in the bottom-performing funds, measured by low *alpha<sub>y-1</sub>*, low  $R^2_{y-1}$  predicts worse rather than better performance. Perhaps in such funds, low  $R^2$  does not indicate selectivity but rather unreasonable idiosyncratic bets.

The results for *InfRatio* as a performance measure are qualitatively similar. Performance is decreasing in  $R^2_{y-1}$  and it increases with *InfRatio*<sub>y-1</sub>. The portfolio of funds with the highest *InfRatio*<sub>y-1</sub> and lowest  $R^2_{y-1}$  has a positive *InfRatio*<sub>y</sub>, 0.02, with t = 6.16. Here, unlike the case of the *alpha*-sorted funds, *InfRatio*<sub>y</sub> is monotonically decreasing in  $R^2_{y-1}$  even for the worst-performing funds by *InfRatio*<sub>y-1</sub>.

#### INSERT TABLE VIII HERE

We repeat the above analysis doing *independent* sorting on  $R^2_{y-1}$  and on *alpha<sub>y-1</sub>*. The results, presented in Table VIII, Panel A, are qualitatively the same. There are two low- $R^2_{y-1}$  portfolios, with the forth and fifth highest *alpha<sub>y-1</sub>*, that have positive and significant *alpha<sub>y</sub>*. In particular, the portfolio of the highest *alpha<sub>y-1</sub>* and the lowest  $R^2_{y-1}$  has average *alpha<sub>y</sub>* of 2.235% with t = 6.21. The results for the independent sorting using *InfRatio* (Panel B) are qualitatively similar. The fund portfolio of the highest-*InfRatio<sub>y-1</sub>* and lowest  $R^2_{y-1}$  has average *InfRatio<sub>y</sub>* of 0.016 with t = 6.03.

## 6. Factors related to funds' $R^2$

We suggest that a fund chooses a strategy, such as the extent of selectivity that we measure by  $R^2$ , which subsequently affects its performance. We now examine whether there are systematic fund characteristics that are associated with the fund's  $R^2$  by regressing  $TR^2$  on *lagged* fund characteristics.

## INSERT TABLE IX HERE

The results in Table IX show that the funds with high expenses have lower  $R^2$ , as evident from the negative and significant coefficient of *Expenses* in model (1). While *Expenses* is lagged, it is quite persistent so the estimated relationship suggests persistent fund policy on expenses and strategy regarding selectivity. More actively-managed funds expend more resources on selectivity and thus incur higher expenses, and at the same time investors are willing to pay more for investing in these funds because of their superior performance. In the fixed-effect regression (model (2)), the coefficient of *Expenses* is practically zero reflecting almost no change over time in the expense ratio that is related to  $R^2$ . The positive coefficient of Log(TNA) in both models means that larger funds hold broader and more diversified portfolio, which increases their  $R^2$ . As the fund size increases, so does its  $R^2$ . Another explanation is due to Koijen's (2008) model of fund managers who derive utility from improving their ranking or status by raising their fund size. He proposes that managers of smaller fund that have room to grow and provide better status have an incentive to "deviate from the pack" and employ active investment strategy. Here, it means that smaller fund employ less benchmark-based policy and more idiosyncratic policy, producing a positive relationship between *TNA* and  $R^2$ . This relationship is weaker as the fund size grows, following the negative coefficient of  $Log(TNA)^2$  (significant only in Model (1)).

Older funds (higher Age) have lower  $R^2$  after controlling for other characteristics, including fund size which is usually grows with fund age. This result suggests that one reason for fund longevity is its greater selectivity (lower  $R^2$ ) which produces better performance. There is negative relationship between  $R^2$  and *Managerial Tenure*, which is consistent with Chevalier and Ellison's (1999, p. 391) suggestion that younger managers tend to herd or "avoid unsystematic risk when selecting their portfolio." Here it means larger  $R^2$  – which is greater proportion of the risk due to systematic risk – for managers with lower tenure.

The effect of past performance (*alpha*) on fund's  $R^2$  has different sign in the two models. Model (1) mostly reflects the  $R^2$ -*alpha* relationship *across* funds. Stable and persistent strategy and performance by funds produces a negative  $R^2$ -*alpha* relationship across funds regardless of which variable lags the other.

The estimated  $R^2$ -lagged *alpha* relationship in the *fixed-effect* Model (2) shows that better performing funds tend to reduce their level of selectivity and do more indexing. (Notably, we control for fund size that is itself affected by past performance.) Our result is consistent with Elton, Gruber and Blake's (2003, p. 785) proposition that funds adopt the following strategies: "Greater risk-taking after a period of underperforming the benchmarks," and "Less risk-taking after periods of outperforming the benchmarks." We obtain that outperforming funds subsequently increase the extent of indexing, or choose higher  $R^2$ , thus taking less idiosyncratic risk. This helps preserve their past good performance in A multi-year performance comparisons, although this strategy is costly: higher  $R^2$  lowers future performance. And, funds that underperform subsequently take more idiosyncratic strategy – choose lower  $R^2$  – in the hope of hitting a successful strategy. For such funds, indexing will preserve their past bad performance and will not give them a chance to improve. The results on the  $R^2$ - lagged performance relationship are qualitatively similar when using *InfRatio* instead of *alpha*, and is not reported here.

The estimation model of the determinants of  $R^2$  includes year dummy variables. The coefficients of these variables generally increase over time. In the first nine years, the

average  $R^2$  is lower than it is in the last nine years, suggesting a growing propensity to follow the indexes over time. The last nine-years, which use different data source and produce more significant negative relationship between performance and  $R^2$ , seem to have different characteristics.

## 7. Conclusion

We propose a convenient, intuitive measure of mutual fund selectivity or active management: the  $R^2$  from a regression of fund return on the Fama-French (1993) and Carhart (1997) factors. We find that the fund  $R^2$ , estimated from one year's daily returns, predicts the following year's fund performance, measured either by the fund's *alpha* or by its *Information Ratio (InfRatio)*, which is the fund *alpha* scaled by the regression's *RMSE*. The predictive coefficient of  $R^2$  is negative and highly significant. That is, lower  $R^2$ , or greater fund activity and selectivity, predicts better performance. We also obtain that the pair of volatility measures which constitute  $R^2$ , *RMSE* and return standard deviation *SDR* (their squared ratio equals 1-  $R^2$ ) predict fund subsequent performance, with positive and negative coefficients, respectively. These effects are obtained after controlling for commonly-used fund characteristics. Our results are the same in both cross-sectional analysis of funds, with year and style fixed effects.

We obtain that the negative predictive effect of  $R^2$  is particularly string for funds with better past performance and for funds whose manager's tenure is shorter. We also find that in predicting *alpha*, the effect of  $R^2$  is greater for funds whose  $R^2$  is in the lower range of its distribution. In predicting *InfRatio*, the negative predictive effect of  $R^2$  is similar in the high and low range of its distribution across funds.

We find that it is possible to identify a portfolio of funds that produces positive and significant performance, measured either by *alpha* or by its *InfRatio*. We sort at the end of each year funds by their  $R^2$  and by their past *alpha* and invest in funds that are in the bottom quintile of  $R^2$  and the highest quintile of *alpha*. The resulting portfolio has an average annual alpha of 2.81% with t = 5.84. Similar results are obtained when replacing *alpha* by the *InfRatio*. The results are similar for independent sorting of funds by their  $R^2$  and past performance.

Fund  $R^2$  is negatively related to another measure of active fund management and idiosyncratic selectivity developed by Cremers and Petajisto (2008), called Active Share, the sum of absolute differences between the portfolio holdings of the fund and its benchmark portfolio. The inclusion of Active Shares in the estimation model leaves the effect of  $R^2$  unchanged.

 $R^2$  is related to identifiable fund characteristics. It is negatively related to expenses, fund age and manager tenure, and positively related to fund size. Importantly, funds react to performance by changing their  $R^2$ . Across funds, funds with better past performance also have lower  $R^2$ . However, in a fund fixed-effect analysis we find that the effect of past performance on  $R^2$  is positive, meaning that following better performance, funds tend to index more to preserve their rank, while worse-performing funds increase subsequently their idiosyncratic risk.

Altogether, this study offers a new convenient way to predict mutual fund performance.

#### **Table I. Summary statistics**

Statistics on actively managed equity mutual funds included in our sample. The Weisenberg and Lipper categories that are included are aggressive growth, growth, growth and income, equity income, growth with current income, income, long-term growth, maximum capital gains, small capitalization growth. Index and sector funds are excluded from the sample. The performance measure *alpha* is the intercept from an annual regression of daily fund excess returns on the factors mkt, smb, hml and momentum, and their lagged values.  $R^2$  is obtained from the above regression, and  $TR^2 = log(\sqrt{R^2/(1-\sqrt{R^2})})$ . The Total Net Assets (*TNA*) in \$mm, *Expenses* and *Turnover* are as of the end of the year. *Age* is fund age, the number of years since the fund was first offered. *Tenure* is the tenure of the manager, the number of years since the current manager took control. *AS* is *Active Share* measure from Cremers and Petajisto (2008). The sample period is from January 1989 to December 2007.

## Table II. Predictive regressions of fund performance: Four-factor alpha

Panel regressions of *alpha*, the intercept from an annual regression of daily fund excess returns on the factors mkt, smb, hml and momentum, and their lagged values. All independent variables are as of the end of the previous year.  $TR^2 = log(\sqrt{R^2/(1-\sqrt{R^2})})$ , where  $R^2$  is obtained from the above regression. *RMSE* is the root mean squared error from this regression and *SDR* is the standard deviation of the daily fund returns over the year. The Total Net Assets (*TNA*) in \$mm, *Expenses* and *Turnover* are as of the end of the years. *Age* is fund age, the number of years since the fund was first offered. *Tenure* is the tenure of the manager, the number of years since the current manager took control. *AS* is *Active Share* measure from Cremers and Petajisto (2008). Each regression also includes year and style dummies, and *t*-statistics in parentheses are based on standard errors clustered by fund. The sample period is from January 1990 to December 2007.

## Table III. Predictive regressions of fund performance: Information Ratio

Panel regressions of the Information Ratio, InfRatio = alpha/RMSE, where alpha is the intercept from an annual regression of daily fund excess returns on the factors mkt, smb, hml and momentum, and their lagged values, and RMSE is the root mean squared error from this regression. All independent variables are as of the end of the previous year.  $TR^2 = log(\sqrt{R^2/(1 - \sqrt{R^2})})$ , where  $R^2$  is obtained from the above regression. SDR is the standard deviation of the daily fund returns over the year. The Total Net Assets (TNA) in \$mm, Expenses and Turnover are as of the end of the year. Age is fund age, the number of years since the fund was first offered. Tenure is the tenure of the manager, the number of years since the current manager took control. AS is Active Share measure from Cremers and Petajisto (2008). Each regression also includes year and style dummies, and t-statistics in parentheses are based on standard errors clustered by fund. The sample period is from January 1990 to December 2007.

## Table V. Fama-MacBeth regressions of fund performance

The dependent variables are *alpha*, the intercept from an annual regression of daily fund excess returns on the factors mkt, smb, hml and momentum and their lagged values and *InfRatio* = *alpha/RMSE*, where *RMSE* is the root mean squared error from this regression. All independent variables are as of the end of the previous year.  $TR^2 = log(\sqrt{R^2/(1-\sqrt{R^2})})$ , where  $R^2$  is obtained from the above regression. *SDR* is the standard deviation of the daily fund returns. The Total Net Assets (*TNA*) in \$mm, *Expenses* and *Turnover* are as of the end of the year. *Age* is fund age, the number of years since the fund was first offered. *Tenure* is the tenure of the manager, the number of years since the current manager took control. The numbers presented are the means of the annual coefficients, the *t*-statistics (in parentheses) and (in brackets) the probability of the null hypothesis being rejected. At the bottom three lines, the numbers in brackets are the probability under null of the coefficient being equally likely positive or negative. The sample period is from January 1990 to December 2007.

# Table VI: Predictive Regressions of fund performance, with high and low split of lagged $TR^2$ , *alpha* and *InfRatio*

Panel regressions of *alpha*, the intercept from an annual regression of daily fund excess returns on the factors mkt, smb, hml and momentum, and their lagged values, and InfRatio = alpha/RMSE. All independent variables are as of the end of the previous year.  $TR^2 = log(\sqrt{R^2/(1-\sqrt{R^2})})$ , where  $R^2$  is obtained from the above regression. The Total Net Assets (TNA) in \$mm, *Expenses* and *Turnover* are as of the end of the year. Age is fund age, the number of years since the fund was first offered. *Tenure* is the tenure of the manager, the number of years since the current manager took control.  $HiDUMR^2$  equals 1 if in year y-1 the fund's  $R^2$  is higher than the cross-sectional median  $R^2$  for that year (zero otherwise).  $HiTR^2=TR^2*HiDUMR^2$  and  $LoTR^2=TR^2*(1-HiDUMR^2)$ . The dummies specifications for Alpha (Lo/Hi) and InfRatio (Lo/Hi) are defined in a similar way. Each regression also includes year and style dummies, and t-statistics in parentheses are based on standard errors clustered by fund. The sample period is from 1/1990 to 12/2007.

## Table VII. Fund Performance, sorting on $R^2$ and *alpha*\InfRatio

The table presents the average portfolio *alphas* or *InfRatio* for year y, based on sorting all fund-year observations in the sample into quintiles by  $R^2$  and within that by *alpha* or *InfRatio* based on year y-1 estimation. *alpha* is the intercept from a regression of daily fund excess returns on the factors mkt, smb, hml and momentum, and their lagged values.  $R^2$  is obtained from this regression. *InfRatio* is *alpha/RMSE* from this regression. Panel A shows the average annualized *alphas* with *t*-statistics in parentheses. Panel B presents the results for *InfRatio*. The sample period is from January 1990 to December 2007.

## Table VIII. Fund Performance: Independent sorting on $R^2$ and *alpha*\InfRatio

The table presents the average portfolio *alphas* or *InfRatio* for year y, based on independent sorting all fund-year observations in the sample into quintiles by  $R^2$  and by *alpha* or *InfRatio* based on year y-1 estimation. *alpha* is the intercept from a regression of daily fund excess returns on the factors mkt, smb, hml and momentum, and their lagged values.  $R^2$  is obtained from this regression. *InfRatio* is *alpha/RMSE* from this regression. Panel A shows the average annualized *alphas* with *t*-statistics in parentheses. Panel B presents the results for *InfRatio*. The sample period is from January 1990 to December 2007.

				$R^{2}_{y-1}$			
alpha <sub>y-1</sub>	Low	2	3	4	High	All	Low- High

## Table IX. Determinants of $TR^2$

Panel regressions of  $TR^2 = log(\sqrt{R^2/(1-\sqrt{R^2})})$ , where  $R^2$  is obtained from the an annual regression of daily fund excess returns on the factors mkt, smb, hml and momentum, and their lagged values. All independent variables are as of the end of the previous year. The performance measure *alpha* is the intercept from the above regression. The Total Net Assets (*TNA*) in \$mm, *Expenses* and *Turnover* are as of the end of the year. *Age* is fund age, the number of years since the fund was first offered. *Tenure* is the tenure of the manager, the number of years since the current manager took control. Each regression also includes style dummy variables and year dummy variables. The *t*-statistics in parentheses are based on standard errors clustered by fund. The sample period is from January 1990 to December 2007.

Variables lagged one year,	(1)	(2)
dummy variables	OLS	Fund fixed effect
Expenses	-0.283	0.006
-	(9.82)	(0.15)
Log(TNA)	0.203	0.129
	(5.26)	(2.99)
$Log(TNA)^2$	-0.011	-0.001
